

Four-wave duration model: paper table

The table compares the repaired four-wave AR(1) model with its two-parameter AR(2) extension on Panel A. Duration-reporting assumptions are unchanged. Table 8 also includes these models' apparent-transition implications.

Table 9: Four-wave duration model: transition rates and recent reversals

	AR(1)	AR(2)
Entry rate	2.693	3.206
Exit rate	4.092	4.775
Misclassification rate	2.646	2.441
Initial employment rate	49.108	49.102
Entry after a recent exit	6.085	18.460
Entry after continued nonemployment	2.547	2.677
Exit after a recent entry	5.860	29.292
Exit after continued employment	3.997	3.989
Log likelihood	-2,894,475.05	-2,892,278.65
N	316,889	316,889
Parameters	33	35

Notes: All rates are percentages. Panel A; four waves; identical samples. Entry and exit rates are survey- and posterior-risk-weighted fitted probabilities pooled across all three quarterly transitions. History-specific rates pool only transitions 2–3 and 3–4; recent means a latent status change in the preceding interval, while continued means no such change. All four reports inform the posterior risk sets; these are not raw observed-switcher rates or real-time forecasts. Groups have different duration compositions. Both models retain the same piecewise duration hazards, duration-reporting mechanisms, and AR(1) first-transition initialization. The proposed new-nonemployment onset restriction and alternative same-employer return treatment have not been implemented. Likelihood weights are normalized to N. Standard errors and calibrated significance tests are pending; no significance stars are reported.

The AR(2) model attributes more turnover to genuine short-lived transitions, while retaining a substantial role for status misclassification. Recent entrants and leavers have much higher next-quarter transition probabilities than people whose status was unchanged in the preceding interval. These comparisons combine duration composition with the estimated history effects; they are not causal effects of switching.

The questionnaire distinction is important: timegap measures time since last work, while tenure is derived from the reported employer/business start date. The current findings remain conditional on the treatment of new nonemployment spells and interruptions followed by return to the same employer. Those sensitivity checks and analytical uncertainty are still pending.
